Assessment of Aerobic Power (Vo₂ Max) in Different Group of Athletic Females in Relation with Body Mass Index and Hemoglobin

Rekha K, Anu S, Antony Selvi S

1Assistant Professor, 2Professor & Head, Department of Physiology, Velammal Medical College, Madurai.
3Associate Professor, Raja's Dental College, Tirunelveli.

ABSTRACT

Introduction: Vo₂ max is one of the most important indicator of determining cardiopulmonary fitness. The present study was done to find out whether exercise training improves Vo₂ max and if so, among which sports group the highest value was observed. The relationship of height, weight and hemoglobin level on Vo₂ max was also studied.

Aim & objectives:
1. To assess and compare the maximal oxygen uptake (Vo₂ max) in different groups of athletic females.
2. To find out the relationship between Vo₂ max, BMI and Hemoglobin concentration in different groups of female athletes.

Materials & Methods: This study was conducted in the physical education department. Randomly selected Forty trained female athletes, between 18-25 years of age without any medical illness were included in the study group which was subdivided into four groups (Volleyball, Basketball, Khokho & Ball badminton) consisting of 10 in each group. Control group consisted of untrained females of the same age group. Vo2 max was determined using Bruce protocol in a treadmill test.

Results: Mean value for the Vo₂ max was found to be less in Control (23.065ml/Kg/min) compared to Study group (p<0.001) and among athletes, Vo₂ max was more in the basket ball (36.367ml/Kg/min) players with the maximum height (163.1cm) than other groups . Hemoglobin values were less in study group compared to the control group (p value < 0.001) No significant difference was observed in BMI between the control and study groups.

Conclusion: Endurance training as well as height significantly influences the aerobic power than the BMI & Hemoglobin concentration.

Key words: Athletes, females, Vo₂ max, BMI, Haemoglobin level

INTRODUCTION:

Exercise is a bodily activity that enhances or maintains the physical fitness and overall health and wellness. It is performed for various reasons including strengthening of muscles and heart, improving athletic skills, weight maintenance, as well as for the purpose of enjoyment. Frequent and regular physical exercise boosts the immune system and prevents the occurrence of heart disease & Type 2 diabetes.

Regular exercise, by increasing flow of blood to various organs of the body, delivers more oxygen, nutrients and thereby improves functioning of the vital organs .The Physiological variables which influence athletic performances are: Vo₂ max, running economy and anaerobic threshold.¹
One of the most important predictors of endurance performance is \( \text{Vo}_{2\text{max}} \). Aerobic power or \( \text{Vo}_{2\text{max}} \) which involves a full functional support from cardio respiratory and metabolic pathways is an appropriate test to study cardio pulmonary fitness. The term “\( \text{Vo2} \)” is derived from V-volume of \( \text{O}_2 \)-oxygen. \( \text{Vo}_{2\text{max}} \) is the maximum volume of oxygen in milliliters that the body can consume in one minute per kilogram of body weight during intense, whole-body exercise. Those who are fit have higher \( \text{Vo}_{2\text{max}} \) values and can exercise more intensely than those who are not as well conditioned.

As exercise intensity increases so does the oxygen consumption. However, a point is reached where exercise intensity can continue to increase without the associated rise in oxygen consumption. The point at which oxygen consumption plateaus defines the \( \text{Vo}_{2\text{max}} \) or an individual's maximal aerobic capacity. Aerobic power, aerobic capacity and maximal oxygen uptake are all terms used interchangeably with \( \text{Vo}_{2\text{max}} \).

\( \text{Vo}_{2\text{max}} \) averages about 33-36 ml/kg/min in active healthy women in the age group of 20-29 years. It is lower in sedentary individuals (less than 23.6 ml/kg/min). Training increases the maximal oxygen consumption (\( \text{Vo}_{2\text{max}} \)) which is the product of maximal cardiac output and maximal \( \text{O}_2 \) extraction by the tissues. It is well established that \( \text{Vo}_{2\text{max}} \) is higher in female athletes when compared to female non-athletes. The present study was done to compare the \( \text{Vo}_{2\text{max}} \) of different group of athletes.

\( \text{Vo}_{2\text{max}} \) varies with age, gender, weight and height. Studies on the effect of body mass index on \( \text{Vo}_{2\text{max}} \) had shown controversial results. Body Mass Index (BMI) is used for screening the health of the general population as there is a strong correlation between being overweight or obese and having health problems, chronic diseases and premature death. Increased BMI levels have also been associated with decrease in respiratory and cardiovascular system capacity resulting in decreased \( \text{Vo}_{2\text{max}} \). Increased BMI was also found to increase \( \text{Vo}_{2\text{max}} \) in physical education students.

\( \text{Vo}_{2\text{max}} \) was affected by hemoglobin concentration which determines the oxygen carrying capacity of the blood. In trained individuals it was expected of them to have high hemoglobin concentration as training increases \( \text{Vo}_{2\text{max}} \).

Hence the present study was done not only to compare the \( \text{Vo}_{2\text{max}} \) of different athletic groups, but also to find out the relationship between BMI, Height and Hemoglobin concentration on \( \text{Vo}_{2\text{max}} \) in trained female athletes.

**AIM AND OBJECTIVES:**

**Aim:**

To assess the maximal oxygen uptake (\( \text{Vo}_{2\text{max}} \)), Body Mass Index (BMI) and Haemoglobin level in different groups of athletic females.

**Objectives:**

1. To compare \( \text{Vo}_{2\text{max}} \) of female athletes in different groups like basket ball, volley ball, Kho-kho and ball badminton.

2. To compare Body Mass Index of female athletes in different groups like basket ball, volley ball, Kho-kho and ball badminton.
3. To compare Haemoglobin levels of female athletes in different groups like basket ball, volley ball, Kho-kho and ball badminton.

4. To find out the relation between $\text{Vo}_2\text{ max}$, Body mass index & Haemoglobin among athletes and control.

**MATERIALS AND METHODS:**

The present study is a comparative study conducted in the physical education department, in a private medical college in Tamilnadu over a period of 3 months after obtaining the Institutional Human Ethical Committee clearance. A total number of 50 subjects were selected randomly from Physical education department.

Study group included forty trained, randomly selected female athletes in the age group of 18-25 years who were subdivided into four groups, consisting of 10 members in each group. Athletic females who were representing university sports team such as Volley ball, Basket ball, Khokho and Ball badminton were selected for the study, after obtaining informed written consent from each individual. 10 athletes were selected from volleyball team, 10 from basketball, 10 from khokho and the remaining 10 from ball badminton team.

Control group included 10 non athletic females of the same age group from Rajah Muthiah medical college, who had no particular athletic background. Healthy female athletes who have been involved in sports activities for more than 2 years were included in the study. Female athletes below 18 and above 25 years, those having history of cardiac, respiratory or neuromuscular diseases and with irregular training were excluded from the study.

**Data Collection Method And Tools:**

Baseline and endline data were collected using a questionnaire. Experiment was conducted in the evening on every day. $\text{Vo}_2\text{ max}$, BMI & Haemoglobin levels were measured initially and then after the treadmill test.

$\text{Vo}_2\text{ max}$ was estimated using a Bruce protocol. The Bruce Protocol is a maximal exercise test where the athlete works to complete exhaustion as the treadmill speed and incline is increased every three minutes. Because this is a maximal exercise test, this test was performed with reasonable safety accommodations and supervision. The length of time on the treadmill is the test score and can be used to estimate the $\text{Vo}_2\text{ max}$ value.

**Treadmill Test:**

Individuals had to run on a treadmill with a starting slope of 0 degree and a speed of 1.7 miles/hr (11 km/hr). The slope was increased at the end of every 3 minute (without taking a pause in the run), till the person is no longer able to continue and the time spent on running was recorded.

**Bruce Treadmill Test Stages**

Stage 1 = 1.7 mph at 0% Grade  
Stage 2 = 1.7 mph at 5% Grade  
Stage 3 = 1.7 mph at 10% Grade  
Stage 4 = 2.5 mph at 12% Grade  
Stage 5 = 3.4 mph at 14% Grade  
Stage 6 = 4.2 mph at 16% Grade  
Stage 7 = 5.0 mph at 18% Grade  

(mph – miles / hour)

From the total run time an estimate of the athlete's $\text{Vo}_2\text{ max}$ was calculated as follows:

For women $\text{Vo}_2\text{ max} = 4.38 \times (T - 3.9)$

"T" is the total time of the test expressed in minutes and fractions of a minute.
Procedure:

1) The assistant sets the treadmill to a speed of 1.7 miles/hour with a slope of 0°.
2) The athlete warms up for 10 minutes.
3) The assistant gives the command "GO"; starts the stopwatch and the athlete commences the test.
4) The assistant, at 3 minutes intervals, adjusts the treadmill slope as per the table below.
5) The assistant stops the stopwatch when the athlete is unable to continue.

Body Mass Index (BMI):

BMI is defined as the individual's body weight divided by the square of his or her height. Formula: Weight (kg) / Height (m²). Weight was recorded in kilograms by using a locally made, calibrated, electronic weighing scale, accuracy +/- 0.01 kg. Height was measured in centimeters while standing erect. Reading was taken nearest to 1 cm by using inch tape.

Blood Hemoglobin level was estimated using Sahli’s Haemoglobinometer based on colour comparison.

RESULTS:

In this study, 50 females between the age group of 18 to 25 years were selected for assessment of $V_o_2 max$, in that 40 were trained athletes (each group consists of 10 people) & 10 were controls. Analysis of results were done using Bonferroni multiple comparison test.

Table 1- Comparison of $V_o_2$ max by grouping

<table>
<thead>
<tr>

Table 4 shows a significant difference (p<0.001) between control and study group regarding hemoglobin levels.

**DISCUSSION:**

Maximal exercise test with direct measurement of oxygen uptake is considered the most accurate method of assessing aerobic power. Exercise stress testing is most commonly carried out using a Treadmill. In the present study, $V_o_2$ max of athletic females engaged in different sports were compared with each other and also with that of controls. Age matched female subjects were chosen for this study as $V_o_2$ decreases with age. The result according to Table 1 states that $V_o_2$ max is more in athletic females (<0.001) when compared to the control group. This result suggests that endurance training has a beneficial effect on increasing the $V_o_2$ max values. Earlier studies also have observed similar findings. This can be explained on the basis of many physiological alterations which occur in the body as a result of long term regular exercise.

There is ample of evidence that training can improve the performance of muscles by many adaptations, including increased density of the capillary network in the skeletal muscles increasing the capacity to irrigate muscles with blood. The changes that occur include over expression of PGC-1α resulting in increase in the number of mitochondria and the enzymes involved in oxidative metabolism. The net effect is more complete extraction of $O_2$ and consequently, for a given work load, less increase in lactate production. In healthy untrained subjects, rapidly increasing lactate levels normally limit exercise tolerance. Less lactate released by the muscles and excess ventilation, together with an increase in the tolerable minute volume, combine to increase the $V_o_2$ max. Regular training increases $V_o_2$ max by increasing cardiac output secondary to increase in stroke volume and an increase in arterio venous oxygen difference.

Regarding $V_o_2$ max among athletes, the values were highest in Basket ball players (Mean : 36.367). The second highest values of $V_o_2$ max were recorded in Khokho players. (Mean : 32.999). The lowest values of $V_o_2$ max were recorded in Ball badminton players, and the mean was 31.978.

Basketball is a fast paced, high energy expenditure game when compared to other games that require endurance, speed, strength and hand-eye coordination. In a comparative study done on physical fitness of football, volleyball, basketball and hockey players, next to the football players higher level of $V_o_2$ max was observed in basket ball players.
In the present study, the highest \(\text{Vo}_2\) max values (p value < 0.020) observed among Basketball players compared to others were found to correlate with their height (Table 2-mean:161.3cms) and this could be due to the increase in the vertical diameter of the lungs, which aids in increased minute volume. Previous studies had observed a similar significant correlation between height and \(\text{Vo}_2\) max in young girls as well as in male swimmers and they attributed this to be due to greater lean body mass and larger lung size in tall individuals.\(^{17,18}\)

Table 3 shows that the Body mass index is high in control group (mean=22.640), when compared to the study group but statistically there is no difference between control & study group. Among study group it is comparatively less in volleyball players & more in Ball badminton players. The Basketball and kho kho players have more or less the same \(\text{Vo}_2\) max values.

One of the problems associated with Body Mass Index is that there is no way to know if the person is heavily muscled or overweight. Therefore, body fat percentage has been recently recommended as a more accurate measurement of body fatness.\(^{19}\) The present study result can be explained on the basis that athletes have more muscle mass contributing to the Body mass index, when compared to controls, where it may be contributed by fat.

There were mixed results regarding BMI and \(\text{Vo}_2\) max.\(^{20,21}\) A negative correlation was observed between BMI and \(\text{Vo}_2\) max and that fitness level decreased with increasing body weight. The proposed mechanism could be that with BMI more than 30, the minimum classification for obesity, the functional residual capacity of the lungs is reduced by 25 percent, expiratory reserve volume is reduced by over 50 percent and decline in several measurements of cardiovascular function are observed. While these functional measurements are not heavily involved in normal breathing, they do drastically limit the lungs' capacity for achieving maximum work and will result in lowered \(\text{Vo}_2\) max values.

Few other studies done to assess the relationship between body fat and \(\text{Vo}_2\) max have concluded that obese females are as fit as non obese females and they do not have less \(\text{Vo}_2\) max.\(^{22,23}\) It was found that in a 14 days fitness programme, the absolute \(\text{Vo}_2\) max was higher in obese than in normal weight women.

The present study result coincides with the results of the study done on \(\text{Vo}_2\) max and body fat percentage in female athletes where Negative correlation was there between \(\text{Vo}_2\) max and body fat percentage but was not statistically significant.\(^{24}\)

Regarding hemoglobin levels, (Table 4) the control group has the highest value (mean=11.340 g%). Among study group volleyball players has the high hemoglobin values, in khokho & ball badminton players it is more or less same, while Basketball players has the low hemoglobin values. A negative correlation was observed between basketball players and all the other groups on hemoglobin & \(\text{Vo}_2\) max.

A reduction of blood hemoglobin concentration characterized by decreased \(O_2\) carrying capacity of blood is expected to decrease \(\text{Vo}_2\). In the present study, the basket ball players exhibiting highest \(\text{Vo}_2\) max among all the other groups have low blood hemoglobin. This could be due to expansion of plasma volume in trained individuals caused by
translocation of fluid from the interstitial compartment and increased albumin synthesis by the liver. The plasma volume expansion is greater than the red blood cell expansion and thereby hemoglobin concentration decreases (Sports or pseudo anaemia).

True anaemia in athletes could be due to iron deficiency, exertional hemolysis, and exercise related gastro intestinal bleeding. It was also reported that \( \text{Vo}_2 \text{max} \) is limited by the availability of \( \text{O}_2 \) and not by the increase in hemoglobin with altitude acclimatization. During maximal exercise neither peak cardiac output nor peak leg blood flow are affected by reduced hemoglobin.

From the above reports, it was observed that \( \text{Vo}_2 \) max values were higher in athletes. BMI has no significant difference between study & control groups. It is also observed that along with endurance training, height of the individual also influences the aerobic power.

**CONCLUSION:**

In the present study, we have concluded that, compared to control group, aerobic power (\( \text{Vo}_2 \text{max} \)) is increased in athletes. Among athletes, \( \text{Vo}_2 \text{max} \) is increased in basketball players, when compared with volleyball, Kho kho & Ball badminton players.

\( \text{Vo}_2 \text{max} \) in the Basketball players is mainly influenced by endurance training and height of the individual, than the lean body mass. Low Haemoglobin concentration observed in athletic group could be due to sports anaemia. Despite the limiting factors, improving \( \text{Vo}_2 \text{max} \) scores is possible, if an appropriate exercise or training regime is followed.
